Week 9: Modeling Volatility (ARCH/GARCH)

Kurtosis

An ARCH(1) specification

$$\varepsilon_t = \sigma_t u_t$$

$$u_t \overset{iid}{\sim} N(0,1)$$

$$\sigma_t^2 = \alpha_0 + \alpha_1 \varepsilon_{t-1}^2.$$

Recall (**Week 8**) unconditional moments of the ARCH(1) model

(**5**.) It can be shown that the kurtosis for ε_t is

$$\kappa = 3 \times \frac{(1-\alpha_1^2)}{(1-3\alpha_1^2)} > 3.$$

when $0 < \alpha_1 < \sqrt{1/3}$ (proof not supplied).

Moments of the ARCH(1) model

- (**5**.) shows that the unconditional distribution of the $\{\varepsilon_t\}$ from an ARCH model **cannot be a normal distribution**... **too much kurtosis**.

- Why is this important?

  1. Returns are not normal.
  2. Tails are too thick; i.e., too much kurtosis.
  3. However, we can use a conditional normal random variable to model returns.
  4. So long as we augment this random variable with ARCH-like characteristics.

Moments of the ARCH(1) model

This means that this simple model allows us to capture two important stylized facts of returns data:

(1) Returns have thick tails, i.e., are not (unconditionally) normal;

(2) Risk (or volatility) is time-varying and autoregressive, i.e., returns display ARCH-like behavior;

Estimation of an ARCH model

- MLE chooses c, ϕ_1, α_0 and α_1 to maximise the (log of the) joint probability of the observed data points in our sample (called the log likelihood (LL)).

- For an ARCH(1) model (with AR(1) mean and normal u_t the LL is given by

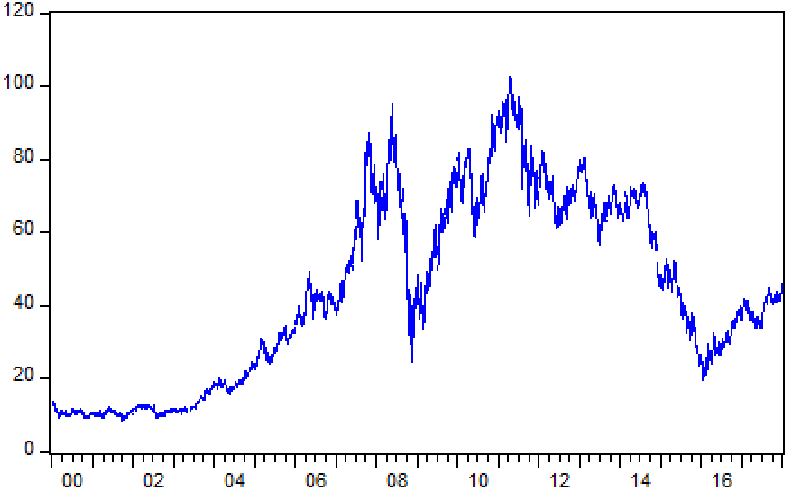
$$-\frac{T}{2}\ln(2\pi) - \frac{1}{2}\sum_{t=1}^{T}\ln\sigma_t^2 - \frac{1}{2}\sum_{t=1}^{T}\frac{(r_t - c - \phi_1 r_{t-1})^2}{\sigma_t^2},$$

  with

$$\sigma_t^2 = \alpha_0 + \alpha_1(r_{t-1} - c - \phi_1 r_{t-2})^2.$$

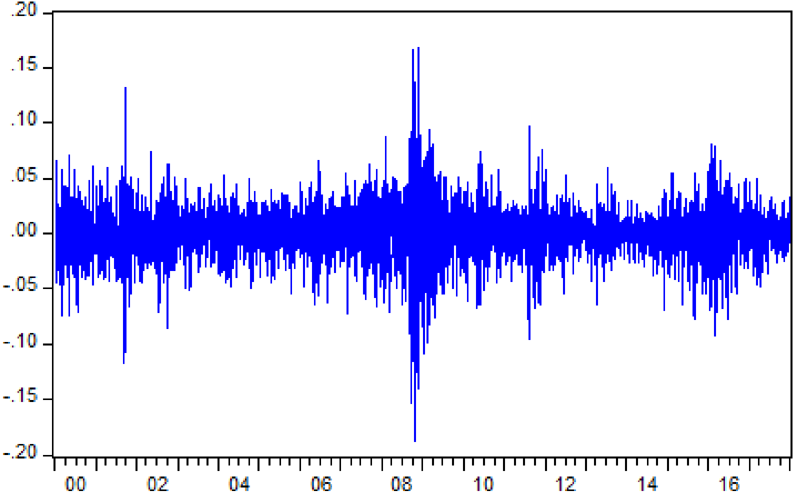
- The form of this LL comes from the AR(1)-ARCH(1) specification and the assumption that $u_t \overset{iid}{\sim} N(0,1)$.

ibm.xts is daily 3 Jan 2000 to 3 Jan 2018



```r
# log return
lret <- na.omit(diff(log(ibm.xts)))
colnames(lret) <- "log return"
```

lret = log return



```r
# AR(1,0)-ARCH(1)

library(rugarch)

spec_arch1 <- ugarchspec(
  variance.model = list(
    model = "sGARCH",             # standard GARCH
    garchOrder = c(1, 0)          # c(ARCH,GARCH)
  ),
  mean.model = list(
    armaOrder = c(1, 0),          # AR(1)
    include.mean = TRUE
  ),
  distribution.model = "norm"   # normal errors
)

# Estimate the AR-GARCH models
fit_arch1 <- ugarchfit(
  spec = spec_arch1,
  data = lret
)
```

Mean-Adjusted AR models

The AR(1) model is written in mean-adjusted form as

$$y_t - \hat{\mu} = \hat{\phi}(y_{t-1} - \hat{\mu}) + \hat{e}_t,$$

where

$$\hat{\mu} = 0.0006500238$$

and

$$\hat{\phi} = 0.0199421101.$$

Mean-Adjusted AR Models

To rewrite the model in the usual intercept form,

$$y_t = c + \phi y_{t-1} + e_t,$$

we expand the mean-adjusted AR(1) model as follows:

$$y_t = \mu + \phi y_{t-1} - \phi\mu + e_t.$$

Therefore,

$$y_t = \mu(1 - \phi) + \phi y_{t-1} + e_t.$$

Hence,

$$c = \mu(1 - \phi).$$

Mean-Adjusted AR Models

Using the estimated values,

$$\hat{c} = 0.0006500238(1 - 0.0199421101),$$

so

$$\hat{c} \approx 0.000637061.$$

Thus, the AR(1) model in the usual intercept form is

$$y_t = 0.00064 + 0.0199421101 y_{t-1} + \hat{e}_t.$$

The unconditional mean is

$$\frac{\hat{c}}{1 - \hat{\phi}} = \frac{0.000637061}{1 - 0.0199421101} = 0.0006500238.$$

Forecasting: an AR(1)-ARCH(1) model

Fitted model for IBM returns:

$$r_t = 0.00064 + 0.01994 r_{t-1} + \hat{\varepsilon}_t,$$

with

$$\hat{\varepsilon}_t = \hat{\sigma}_t \hat{u}_t,\ \hat{\sigma}_t^2 = 0.00041 + 0.30427 \hat{\varepsilon}_{t-1}^2.$$

LL (Log likelihood) = 10638.59

Daily IBM log returns: 4 Jan 2000 to 3 Jan 2018 (4529 obs)

Let's forecast 4 Jan 2018

$\mathcal{F}_{4529}$: We have:

$r_{4529} = 0.004$, $\widehat{\varepsilon}_{4529} = 0.0027$, $\widehat{\sigma}^2_{4529} = 0.00073$, and $P_{4529} = \$47.71$.

Forecasting with an AR(1)-ARCH(1) model

Forecasts:

Conditional mean:

$$\begin{aligned}\widehat{E}[r_{4530}|\mathcal{F}_{4529}] &= 0.00064 + 0.01994 \times (0.004) \\ &= 0.0007\end{aligned}$$

Conditional variance:

$$\begin{aligned}\hat{\mathbb{V}}[r_{4530}|\mathcal{F}_{4529}] &= \hat{\mathbb{V}}[\varepsilon_{4530}|\mathcal{F}_{4529}] \\ &= 0.00041 + 0.30427 \times (0.0027)^2 \\ &= 0.00041\end{aligned}$$

$\Rightarrow$ Volatility:

$$\widehat{\sigma}_{4530}[r_{4530}|F_{4529}] = \sqrt{0.0004} = 0.02$$

Forecasting using R

```r
# h-step ahead forecast
h <- 1
fc_arch1 <- ugarchforecast(fit_arch1, n.ahead = h)

# Mean forecasts
mu_fc_arch1 <- as.numeric(fitted(fc_arch1))
mu_fc_arch1

# Volatility forecasts
sigma_fc_arch1 <- as.numeric(sigma(fc_arch1))
sigma_fc_arch1
# Variance forecasts
var_fc_arch1 <- sigma_fc_arch1^2
var_fc_arch1
```

Forecasting with an AR(1)-ARCH(1) model

If we assume that $u_t \sim N(0,1)$ so that $\varepsilon_t|\mathcal{F}_{t-1} \sim N(0,\sigma_t^2)$ then the conditional distribution of returns will also be normally distributed.

We can compute the 95% prediction interval for the one-step-ahead forecast of r_t.

A 95% prediction interval for r_{4530} would be

$$0.0007166364 \pm 1.96 \times 0.02032072$$

giving the interval

$$[-0.0391, 0.0405]$$

Forecasting with an AR(1)-ARCH(1) model

If we assume that $u_t \sim N(0,1)$ so that $\varepsilon_t | \mathcal{F}_{t-1} \sim N(0, \sigma_t^2)$ then the conditional distribution of returns will also be normally distributed.

Recall $P_{4529} = \$47.71$

We can form prediction intervals for the **next price**

A 95% prediction interval for P_{4530} is

$$\left[\$47.71e^{-0.0391},\ \$47.71e^{0.0405}\right] = [\$45.88,\ \$49.68]$$

Diagnostics for an ARCH model

- We can use the ARCH LM test to determine if serial correlation in $\widehat{u}_t^2$ remains.
  - if there appears to be serial correlation remaining in the squared residuals,
  - $\Rightarrow$ we can improve the volatility model by including more ARCH terms.

ARCH test

```
> res_s.arch1    <- residuals(fit_arch1, standardize = TRUE)
> FinTS::ArchTest(res_s.arch1, lags = 4)

        ARCH LM-test; Null hypothesis: no ARCH effects

data:  res_s.arch1
Chi-squared = 303.02, df = 4, p-value < 2.2e-16
```

ARCH(q)

1. In many cases we can improve our volatility model by working with an ARCH(q) model.

2. ARCH(q) takes $\varepsilon_t = u_t \sigma_t, \; u_t \sim i.i.d.N(0,1)$ and

$$\sigma_t^2 = \alpha_0 + \alpha_1 \varepsilon_{t-1}^2 + \ldots + \alpha_q \varepsilon_{t-q}^2.$$

- In many cases, especially with **higher frequency data**, we need q to be very large;

    1. Otherwise $\widehat{u}_t^2$ will be auto-correlated.
    2. Suggests that we could improve our modeling of conditional variance.
    3. This can be solved using GARCH models (generalized ARCH).

- The $\widehat{u}_t$ do not appear to have come from a normally distributed u_t.

    1. Can be fixed by changing the assumptions about u_t.
    2. E.g., to get more kurtosis, we could assume that the u_t have a t-distribution.
    3. This involves maximising a different likelihood.

Student-t Distribution

```
> fit_arch1_t@fit$matcoef
           Estimate   Std. Error   t value    Pr(>|t|)
mu      0.0007977183 2.906414e-04  2.744682 0.006056951
ar1    -0.0201519356 1.689249e-02 -1.192952 0.232888013
omega   0.0004235392 1.834514e-05 23.087267 0.000000000
alpha1  0.2881657780 3.291013e-02  8.756143 0.000000000
shape   5.0133763383 3.739183e-01 13.407680 0.000000000
```

Student-t Distribution

In 'rugarch' with *distribution.model* = *"std"*, the parameter *shape* is the degrees of freedom v of the Student-t distribution for the model errors.

In the R output: *shape* = $5.0134 \approx 5$

What that means:
Smaller $v \rightarrow$ heavier tails $\rightarrow$ more probability of large shocks/outliers than Normal.

As $v \rightarrow \infty$ Student-t approaches the Normal.

So $v \approx 5$ is heavy-tailed (typical for financial returns).

GARCH models

ARCH models have difficulty modelling the autocorrelation in the squared residuals.

GARCH models generalise ARCH models to include lags of σ_t^2 in the conditional variance equation as well as lags of ε_t^2, and this often alleviates this difficulty.

A GARCH(p,q) model is given by

$$\sigma_t^2 = \alpha_0 + \alpha_1 \varepsilon_{t-1}^2 + \ldots + \alpha_q \varepsilon_{t-q}^2 + \beta_1 \sigma_{t-1}^2 + \ldots + \beta_p \sigma_{t-p}^2.$$

GARCH models

A GARCH(p,q) model

$$\sigma_t^2 = \alpha_0 + \alpha_1 \varepsilon_{t-1}^2 + \ldots + \alpha_q \varepsilon_{t-q}^2 + \beta_1 \sigma_{t-1}^2 + \ldots + \beta_p \sigma_{t-p}^2.$$

We assume that
(i) all $\alpha_i > 0$ and all $\beta_j > 0$ to ensure that $\sigma_t^2 > 0$, and

(ii) that $\sum_{i=1}^q \alpha_i + \sum_{j=1}^p \beta_j < 1$ to ensure that $\mathbb{V}(\varepsilon_t) > 0$.

The α_i and β_j determine how past news affect current volatility and this persistence is often measured by $\gamma = \sum_{i=1}^q \alpha_i + \sum_{j=1}^p \beta_j$.

If α_0 is the only non-zero parameter then we have constant volatility.

Conditional moments of GARCH(p,q) errors

Recall that $\varepsilon_t = \sigma_t u_t$ with $u_t \sim N(0,1)$, so the standardised error, $\frac{\varepsilon_t}{\sigma_t} \sim N(0,1)$ and the conditional distribution $\varepsilon_t | \mathcal{F}_{t-1} \sim N(0, \sigma_t^2)$.

Thus:

1. $E(\varepsilon_t | \mathcal{F}_{t-1}) = 0$
2. $\mathbb{V}(\varepsilon_t | \mathcal{F}_{t-1}) = \sigma_t^2 = \alpha_0 + \sum_{i=1}^{q} \alpha_i \varepsilon_{t-i}^2 + \sum_{j=1}^{p} \beta_j \sigma_{t-j}^2$
3. $Cov(\varepsilon_t, \varepsilon_{t-k} | \mathcal{F}_{t-1}) = 0$ for $k \geq 1$
4. The skewness of $\varepsilon_t | \mathcal{F}_{t-1}$ is zero; and
5. The kurtosis of $\varepsilon_t | \mathcal{F}_{t-1}$ is 3.

All but point 3 follow directly from the fact that $\varepsilon_t | \mathcal{F}_{t-1} \sim N(0, \sigma_t^2)$.

Conditional moments of GARCH(p,q) errors

The proof for point 3 relies on the fact that ε_{t-k} is known at time $t-1$ so

$$Cov(\varepsilon_t, \varepsilon_{t-k}|\mathcal{F}_{t-1}) = E(\varepsilon_t \varepsilon_{t-k}|\mathcal{F}_{t-1}) = \varepsilon_{t-k} E(\varepsilon_t|\mathcal{F}_{t-1}) = 0.$$

Unconditional moments of the GARCH(p, q) errors

(1) $E(\varepsilon_t) = 0$

(2) $\mathbb{V}(\varepsilon_t) = \alpha_0 / (1 - \sum_{i=1}^{q} \alpha_i - \sum_{j=1}^{p} \beta_j)$

(3) $Cov(\varepsilon_t, \varepsilon_{t-k}) = 0$ for all $k \geq 1$

(4) $E(\varepsilon_t^3) = 0$

(5) It can be shown that kurtosis $\kappa > 3$ (proof not supplied).

Unconditional moments of the GARCH(p, q) errors

(1) $E(\varepsilon_t) = 0$

Proof.

$E(\varepsilon_t) = E[E(\varepsilon_t|\mathcal{F}_{t-1})]$ by the L.I.E., and since $\varepsilon_t|\mathcal{F}_{t-1} \sim N(0, \sigma_t^2)$ it follows that $E(\varepsilon_t|\mathcal{F}_{t-1}) = 0$.

Therefore $E(\varepsilon_t) = E(0) = 0$.

$\square$

(2) $\mathbb{V}(\varepsilon_t) = \alpha_0/(1 - \sum_{i=1}^{q} \alpha_i - \sum_{j=1}^{p} \beta_j)$

Proof.

We first note that $E(\varepsilon_t) = 0$ implies that $\mathbb{V}(\varepsilon_t) = E(\varepsilon_t^2)$, and then by the L.I.E.

$$E(\varepsilon_t^2) = E[E(\varepsilon_t^2|\mathcal{F}_{t-1})] = E(\sigma_t^2).$$

Next we note that since $\varepsilon_t|\mathcal{F}_{t-1} \sim N(0, \sigma_t^2)$ and $E(\varepsilon_t|\mathcal{F}_{t-1}) = 0$, it follows that $\sigma_t^2 = \mathbb{V}(\varepsilon_t|\mathcal{F}_{t-1}) = E(\varepsilon_t^2|\mathcal{F}_{t-1})$. Hence

$$\begin{aligned}
\mathbb{V}(\varepsilon_t) &= E(\varepsilon_t^2) \\
&= E(\sigma_t^2) \\
&= \alpha_0 + \sum_{i=1}^{q} \alpha_i E(\varepsilon_{t-i}^2) + \sum_{j=1}^{p} \beta_j E(\sigma_{t-j}^2).
\end{aligned}$$

$\square$

Proof.
But $E(\varepsilon_{t-i}^2) = E(\sigma_{t-j}^2) = \mathbb{V}(\varepsilon_t)$ since ε_t is stationary, so

$$\mathbb{V}(\varepsilon_t) = \alpha_0 + \mathbb{V}(\varepsilon_t)\left[\sum_{i=1}^{q}\alpha_i + \sum_{j=1}^{p}\beta_j\right].$$

Solving this, we get

$$\mathbb{V}(\varepsilon_t) = \alpha_0 \Big/ \left(1 - \sum_{i=1}^{q}\alpha_i - \sum_{j=1}^{p}\beta_j\right).$$

$\square$

Unconditional moments of the GARCH(p,q) errors (cont)

(3) $Cov(\varepsilon_t, \varepsilon_{t-k}) = 0$ for all $k \geq 1$

Proof.

Note

$$Cov(\varepsilon_t, \varepsilon_{t-k}) = E[(\varepsilon_t - E(\varepsilon_t))(\varepsilon_{t-k} - E(\varepsilon_{t-k}))] = E[(\varepsilon_t)(\varepsilon_{t-k})],$$

since $E(\varepsilon_t) = E(\varepsilon_{t-k}) = 0$. Further, the L.I.E. implies that

$$E[(\varepsilon_t)(\varepsilon_{t-k})] = E[E\{\varepsilon_t \varepsilon_{t-k}\}|\mathcal{F}_{t-1})].$$

Next we note that $\varepsilon_{t-k}|\mathcal{F}_{t-1}$ is known for $k \geq 1$, so

$$E[E\{\varepsilon_t \varepsilon_{t-k}\}|\mathcal{F}_{t-1})] = E[(\varepsilon_{t-k})E\{\varepsilon_t|\mathcal{F}_{t-1}\}] = 0,$$

(since $E\{\varepsilon_t|\mathcal{F}_{t-1}\} = 0$.)

$\square$

Unconditional moments of the GARCH(p,q) errors (cont)

(4) $E(\varepsilon_t^3) = 0$

Proof.

We firstly note that, by the L.I.E.,

$$E(\varepsilon_t^3) = E[E(\varepsilon_t^3 | \mathcal{F}_{t-1})].$$

Next under the assumption that $u_t \sim i.i.d.N(0,1)$, we have

$$\varepsilon_t | \mathcal{F}_{t-1} \sim N(0, \sigma_t^2) \text{ and } E(\varepsilon_t^3 | \mathcal{F}_{t-1}) = 0.$$

Then, $E(\varepsilon_t^3) = E[E(\varepsilon_t^3 | \mathcal{F}_{t-1})] = E[0] = 0 \implies$ unconditional distribution is symmetric. $\square$

Unconditional moments of the GARCH(p,q) errors (cont)

(5) It can be shown that kurtosis $\kappa > 3$ (proof not supplied).

- Clearly this should be true.
- If $\beta = 0$, we get back $ARCH(1)$.
- ARCH(1) has $\kappa > 3$.
- Therefore, for $0 \leq \beta \leq 1$, GARCH(1,1) has $\kappa > 3$.

GARCH(p,q) Models

- What conditions are needed to ensure $\sigma_t^2 > 0$?
  1. $\alpha_0 > 0$;
  2. $\alpha_i \geq 0$;
  3. $\beta_j \geq 0$;

- For GARCH(1,1)model:

$$\epsilon_t = \sigma_t u_t \quad \sigma_t^2 = \alpha_0 + \alpha_1 \epsilon_{t-1}^2 + \beta_1 \sigma_{t-1}^2,$$

  this amounts to
  1. $\alpha_0 > 0$;
  2. $\alpha_1 \geq 0$;
  3. $\beta_1 \geq 0$;

Estimation of a GARCH model

- OLS does not provide optimal estimators in this setting so we use MLE (maximum likelihood estimation), as for ARCH models.
- How to estimate GARCH models in R?

```r
# ARMA(1,0)-GARCH(1,1)

spec_garch11 <- ugarchspec(
  variance.model = list(
    model = "sGARCH",            # standard GARCH
    garchOrder = c(1, 1)         # c(ARCH,GARCH)
  ),
  mean.model = list(
    armaOrder = c(1, 0),         # AR(1)
    include.mean = TRUE
  ),
  distribution.model = "norm"
)

# Estimate the ARMA-GARCH models
fit_garch11 <- ugarchfit(
  spec = spec_garch11,
  data = lret
)
```

```
> fit_garch11@fit$matcoef
            Estimate   Std. Error    t value   Pr(>|t|)
mu      5.420103e-04 2.746391e-04   1.973537 0.04843443
ar1    -2.770662e-02 1.553571e-02  -1.783414 0.07451887
omega   5.565428e-06 2.361384e-06   2.356851 0.01843066
alpha1  6.528361e-02 7.364966e-03   8.864074 0.00000000
beta1   9.243447e-01 9.173868e-03 100.758445 0.00000000
```

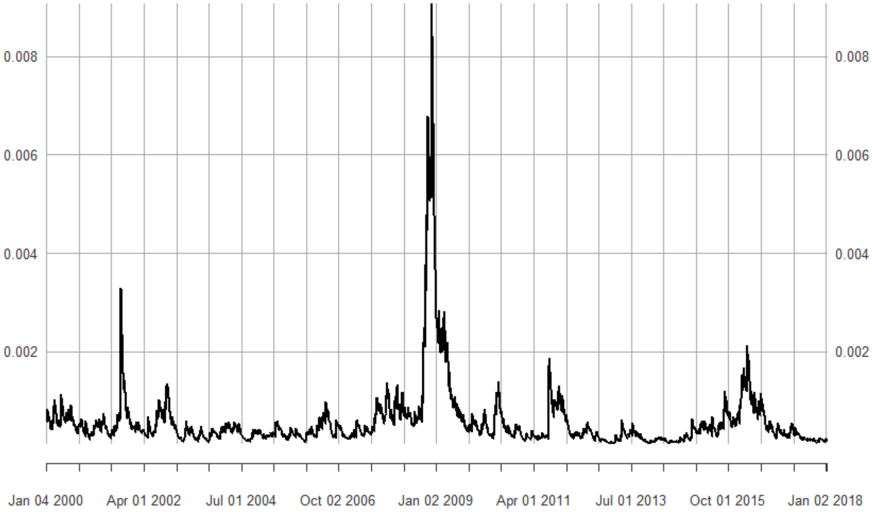
Estimated (Fitted) Conditional Variance

```
sigma2hat_garch11 <- sigma(fit_garch11)^2
tail(sigma2hat_garch11)

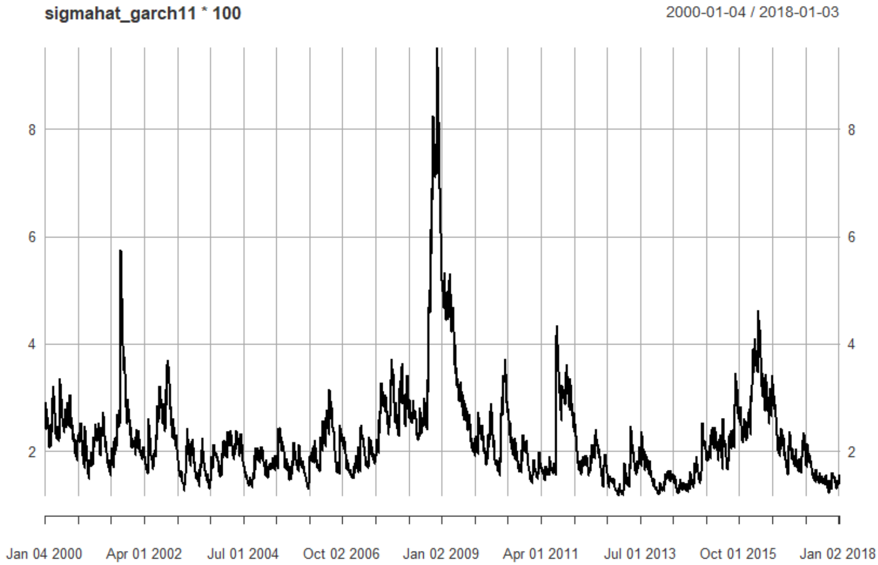
plot(sigma2hat_garch11)

plot(sigma(fit_garch11)*100)
```

Estimated (fitted) Conditional Variance



Estimated (Fitted) Conditional Volatility



Comments on our GARCH(1,1) model

$\widehat{\alpha}_1 \ll \widehat{\beta}_1$. This is typical of GARCH(1,1) models.

Persistence $\widehat{\gamma} = \widehat{\alpha}_1 + \widehat{\beta}_1 = 0.06528 + 0.92434 = 0.98962$

$$\widehat{\mathbb{V}}(\varepsilon_t) = \frac{\widehat{\alpha}_0}{1 - \widehat{\alpha}_1 - \widehat{\beta}_1} = \frac{5.565 \times 10^{-6}}{1 - 0.98962} = \frac{0.000005565}{0.01038} = 0.000537.$$

Long run variance

The implied long run variance is 0.000537 and thus the implied long run volatility is

$$\sqrt{\frac{5.565 \times 10^{-6}}{1 - 0.98962}} = \sqrt{0.000537} = 0.02317.$$

So the unconditional volatility is about 2.32%.

Long-Run Volatility

Although financial markets may experience excessive volatility every now and again, volatility appears to eventually settle down to a long run level. The long run level is the unconditional variance.

For the GARCH(1,1) model the long-run variance is

$$\mathbb{V}(\varepsilon_t) = \frac{\alpha_0}{1 - \alpha_1 - \beta_1}.$$

In this case, the volatility is always pulled toward this long run level; that is volatility 'mean reverts' to its long-run level.

```
> # ehat
> res_garch11 <- residuals(fit_garch11)
> colnames(res_garch11) <- "ehat GARCH"
> tail(res_garch11)

```

Forecasting with an AR(1)-GARCH(1,1) model

Estimated model:

$r_t = 0.000557 - 0.0277 r_{t-1} + \hat{\varepsilon}_t,\ \hat{\varepsilon}_t = \hat{\sigma}_t \hat{u}_t,$

$\hat{\sigma}_t^2 = .0000056 + 0.06528 \hat{\varepsilon}_{t-1}^2 + 0.92434 \hat{\sigma}_{t-1}^2.$

LL (Log likelihood) = 11045.76

Daily IBM log returns: 4 Jan 2000 to 3 Jan 2018 (4529 obs)

$\mathcal{F}_{4529}$: $r_{4529} = 0.004$, $\widehat{\varepsilon}_{4529} = 0.00434$, $\widehat{\sigma}_{4529}^2 = 0.000247$

Forecasting with an AR(1)-GARCH(1,1) model

- One-step ahead forecast of r_t:
- $E[r_{4530}|\mathcal{F}_{4529}] = 0.000557 - 0.0277 \times (0.004) = 0.0004$
- $\mathbb{V}[r_{4530}|\mathcal{F}_{4529}] = \mathbb{V}[\varepsilon_{4530}|\mathcal{F}_{4529}] = 0.0000056 + 0.06528 \times (0.00434)^2 + 0.92434 \times (0.000247) = 0.000235$
- so $\sqrt{\mathbb{V}[r_{4530}|\mathcal{F}_{4529}]} = \sqrt{0.000235}$ =0.0153

Forecasting using R

```
> h <- 1
> fc_garch11 <- ugarchforecast(fit_garch11, n.ahead = h)
>
> # Mean forecasts
> mu_fc_garch11 <- as.numeric(fitted(fc_garch11))
> mu_fc_garch11
[1] 0.0004464693
>
> # Volatility forecasts
> sigma_fc_garch11 <- as.numeric(sigma(fc_garch11))
> sigma_fc_garch11
[1] 0.01534457
> # Variance forecasts
> var_fc_garch11 <- sigma_fc_garch11^2
> var_fc_garch11
[1] 0.0002354558
```

Our model $\Rightarrow E[r_{4530}|\mathcal{F}_{4529}] = 0.0004$ & $\sigma[r_{4530}|\mathcal{F}_{4529}] = 0.0153$

If we then assume that $u_t \sim N(0,1)$ so that $\varepsilon_t|\mathcal{F}_{t-1} \sim N(0,\sigma_t^2)$ then the conditional distribution of returns will also be normally distributed.

Compute the 95% prediction interval for the one-step-ahead forecast of r_t as

$$0.0004464693 \pm 1.96 \times 0.01534457 \implies [-0.0296, 0.0305]$$

ARCH vs GARCH prediction intervals

One-step-ahead prediction interval for ARCH(1) is

$$[-0.03911125, 0.04054452]$$

One-step-ahead prediction interval for GARCH(1,1) is

$$[-0.0296, 0.0305]$$

So GARCH(1,1) has the narrower one-step ahead prediction interval than ARCH(1).

Comparing ARCH/GARCH Models

- Likelihood Ratio test.

- ARCH(q) models are nested in GARCH(p,q) models:
  1. $\beta_1 = \cdots = \beta_p = 0 \implies ARCH(q)$.
  2. Can jointly test for significance of β_js

- If the ARCH specification in question is nested in the GARCH model, can use:

$$\text{LR} = 2 * \left(\text{LL}(\hat{\theta}_G) - \text{LL}(\hat{\theta}_A)\right)$$

  1. $\text{LL}(\hat{\theta}_G)$: likelihood from GARCH model
  2. $\text{LL}(\hat{\theta}_A)$: likelihood from ARCH model
  3. Asymptotically χ^2_p under the null that the models are the same.

name@fit$LLH

```
> # log likelihood for ARCH(1)
> LogL_arch    <- fit_arch1@fit$LLH
> cat("LogLikelihood : ARCH", LogL_arch, "\n")
LogLikelihood : ARCH 10638.59
>
>
> # log likelihood for GARCH(1,1)
> LogL_garch    <- fit_garch11@fit$LLH
> cat("LogLikelihood : GARCH", LogL_garch, "\n")
LogLikelihood : GARCH 11045.76
```

Comparing ARCH/GARCH Models Example

- ARCH(1) versus GARCH(1,1)
- IBM daily returns
- $\text{LL}(\hat{\theta}_A) = 10638.59$
- $\text{LL}(\hat{\theta}_G) = 11045.76$
- $\text{LR} = 2 * (11045.76 - 10638.59) = 814.34$
- $\text{LR} \rightarrow \chi_1^2$ under the null that ARCH(1)=GARCH(1,1); i.e., $\beta_1 = 0$
- Reject this null.
